Abstract

The COVID-19 pandemic continues to be a worldwide public health concern. Although vaccines against this disease were rapidly developed, vaccination uptake has not been equal across 11 all the segments of the population. In particular, it has been shown that there have been 12 differences in vaccine uptake across different segments of the population. However, there are 13 also differences in vaccination across geographical areas, which might be important to consider 14 in the development of future public health policies against COVID-19. In this study, we examined the relationship between vaccination status (having received the first dose of a COVID-19 vaccine), and different socio-economic and geographical factors. Our results show that during 17 the last three months of 2021, individuals in certain equity-deserving groups (visible minori-18 ties) were three times less likely to be vaccinated than White/Caucasian individuals across the 19 province and that in some cases, within these groups individuals in low income brackets had 20 significantly higher odds of vaccination when compared to their peers in high income brackets. 21 Finally, we identified significantly lower odds of vaccination in the West Health Region of Ontario within certain equity-deserving groups. This study shows that there is an ongoing need to better understand and address differences in vaccination uptake across diverse segments of the population of Ontario that have been largely impacted by the pandemic.

²⁷ Covid-19, vaccination, survey, socio-economic factors, visible minorities.

28 Background

As of May of 2023 there have been 765 million confirmed cases of COVID-19 around the world, including 6.8 million deaths¹. Although this disease is no longer categorized as a global health emergency by the World Health Organization (WHO)², there is ongoing concern due to continued transmission, surges in cases and deaths due to new variants³, and weaknesses in health systems around the world that could be exploited by a novel virus or another public health emergency in the future⁴.

In particular, a major weakness that has received attention during the pandemic has been related to inequalities in vaccine uptake. The rapid development of vaccines against COVID-19 initially brought the hope of a rapid end to the pandemic due to the start of vaccination campaigns in certain parts of the world toward the end of 2020^{5–8}) but inequalities in vaccine uptake made these pharmaceutical interventions ultimately unable to replicate the experience of smallpox, where vaccination on a global scale and was crucial to control this disease⁹.

This problematic is a multifaceted issue resulting from a combination of factors, among which are failed public health measures¹⁰, inequality in vaccine access between high- and low-income countries^{11,12}, and vaccine hesitancy¹³. Furthermore, it is well established that this issue has affected in particular individuals in certain equity-deserving groups (e.g., Black, Asian, or Indigenous) as well as individuals with socio-economic disadvantages^{14–20}.

Reasons given for this inequality have included medical mistrust due to systemic medical racism^{16,21}, mistrust in vaccines¹⁴, and the influence of conspiracy theories^{21–23}. However, it is important to also consider that vaccination uptake can be influenced by geographical (spatial) factors. In this regard, differences in COVID-19 vaccination rates have been associated with varied regional attitudes towards vaccination²⁴, spatial differences in vaccine access and supply, vaccination location availability, and lack of prioritization of areas where vulnerable groups reside^{7,25}. Other studies have also shown heterogeneity in vaccine uptake within small governmental administrative units such as counties^{26–29}, and that accounting for geographical differences in vaccination can help predict patterns of booster uptake³⁰.

However, such analyses have been carried mostly in territories outside of Canada, where available studies have been focused in certain cities (such as Toronto³¹, or Montreal³²), or have explored differences at a province-wide level¹⁸. Therefore, there is a need for studies that explore spatial differences in vaccination within the Canadian territory and that consequently, can help identify disparities that need to be addressed within specific areas in each province.

Between 2007 and 2019, Ontario provided healthcare access to its inhabitants using 14 intraprovincial divisions called the Local Health Integrated Networks (LHINs). However, this 61 approach was complex and bureaucratic, resulting in excessive expenditures, disparities in mortality rates, and the deterioration of certain performance indicators such as wait times 63 and readmissions³³⁻³⁵. In an effort to improve the healthcare system of the province, in late 64 2019 the government dissolved the 14 LHINs and the areas they covered were incorporated into 65 6 Health Regions (North East, North West, Central, Toronto, West, and East)³⁵. Due to the 66 relatively recent adoption of the Health Region model and its alignment with the onset of the 67 COVID-19 pandemic, there is a need to analyze if there are ongoing disparities in health access under this approach that need to be addressed before they are exploited by a new disease or public health threat. In this regard, previous research has highlighted disparities in the level of activity of each Health Region³⁶. Therefore, analyzing differences in vaccination uptake 71 within the Health Regions and can help identify which socio-demographic groups are the most 72 vulnerable and what areas of the province deserve special attention by decision-makers. 73

Therefore, in this study we hypothesized that there were differences in vaccination uptake between the different Health Regions of Ontario between October of 2021 and January of 2022. By including socio-economic factors in our analysis, we aimed at identifying in which groups these differences were significant in order to provide an assessment of the current state of healthcare access in Ontario.

79 Methods

80 Data and Methods

We used data from the Survey of COVID-19 related Behaviours and Attitudes, a repeated 81 cross sectional survey focused on the Canadian province of Ontario that was commissioned by the Fields Institute for Research in Mathematical Sciences and the Mathematical Modelling of 83 COVID-19 Task Force under ethical guidance from the University of Toronto, and which ran between September 30th, 2021 and January 17th, 2022. The survey collected socio-economic information from participants (Table 1), their location (nearest municipality, as shown in Figure 1), the date of access to the survey, and asked information on vaccination status by using 87 the question "Have you received the first dose of the COVID vaccine?", with possible answers 88 "yes" and "no". The original dataset contained 39,029 observations (where each observation 89 corresponded to a unique respondent). 90

Preliminary analyses of the data included the removal of outliers (should we still do this?
it's only 19 observations with income >110k and household of 1, but we are
not even using such income bracket in the analysis because we re-grouped the
data, and the household size variable has 90% missing rate), of observations where
respondents did not provide answers in all the covariates of interest, matching the city of each
observations with its corresponding LHIN and Health Region, and removing observations from

areas with low representation (107 observations corresponding to the North West and North East Health Regions). After all the preliminary analyses indicated above, the total number of observations used for analysis was 3,549 which included the East, Central, Toronto, and West Health Regions covering the period between October 1st,2021 and December 12th, 2021. The original dataset, clean dataset, and details on the data cleaning process are described in detail in the GitHub repository for this paper.

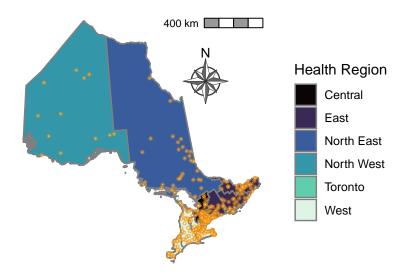

Figure 1: Geographic representation of the data collected by the Survey of COVID-19 related Behaviours and Attitudes, collected by the Fields Institute in Ontario. The municipalities (cities) from where survey participants provided answers (in the clean dataset) appear as points. The Health six Regions are color-coded. Internal boundaries within certain Health Regions indicate areas that belonged to the Local Integrated Health Networks (LHINs), the geographic areas for healthcare in Ontario before the adoption of the Health Regions.

103 Statistical analyses

104

105

106

107

108

109

110

We used a logistic regression model to examine the impact of the Health Regions in vaccination rates while considering the socio-economic factors and and months covered by the survey (Table 1) and certain interactions (Race and Health Region and Race and income), as previous studies have shown that socio-economic factors and their interactions are significant predictors of intent of vaccination and vaccination status^{37–39}. Because we identified differences in representativity between the survey data and the estimates from the Census, we used an iterative proportional fitting procedure $(raking)^{40}$ to correct the data using data from the Census and Health Region population totals; and fitted the regression model to the uncorrected and cor-

rected data. Details regarding the correction can be found in the Appendix. All analyses were conducted in R 4.2.2 using the packages survey⁴¹,tidyverse⁴², quarto⁴³, modelsummary⁴⁴, and gtsummary⁴⁵.

115 Results

116 Sample Characteristics

Table 1 shows the characteristics of the data from the Fields COVID-19 survey used for analysis. The sample contained **6,236** observations, from which 24.8% (1,547) corresponded to individuals that reported not having received the first dose of the vaccine. Vaccination rates ranged between 71-79% across household income brackets, age groups, Health Regions, and the months considered in the survey. However, the highest vaccination rates in each category were reported by individuals in the highest income bracket (79%), those between 16 and 34 years of age (77%), individuals that lived in the East Health Region (77%), and during January of 2022 (78%). Differences were higher between racial/ethnic groups, where the higher vaccination rate was reported by White/Caucasian individuals (84%), against vaccination rates between 63-66% reported in the case of Arab/Middle Eastern, Black, Indigenous, Latin American individuals, and those that reported belonging to "Other" racial groups, which included Southeast Asian, Filipino, West Asian, and minorities not identified elsewhere.

Multivariate Regression

Figure 2 presents the estimates (as odd ratios) from the logistic regression models for vaccina-131 tion status using the socio-demographic factors collected by the survey, and their interactions. 132 Generally speaking, lower odds of vaccination were identified in both cases in individuals characterized by a low household income, or that identified as part of equity-deserving groups. 134 However, the magnitude of the estimates differed between the uncorrected and corrected mod-135 els and more importantly, certain estimates were not deemed to be statistically-significant 136 after the correction, in contrast to the estimates from the uncorrected model. Specifically, the 137 corrected model showed no significant differences in vaccination odds between the age groups 138 considered, the East Health Region, Latin American individuals with a household income under 139 CAD 25,000, and Indigenous individuals living in the Central Health Region (Figure 2,B). 140

However, significantly lower odds of vaccination were identified in the corrected model for those 141 with a household income under CAD 25,000 (OR=0.37, CI=[0.27,0.51]) and those with an 142 income between CAD 25,000 and 59,999 (OR=0.58, CI=[0.42,0.81]). Additionally, individuals 143 who identified as Arab/Middle Eastern, Black, Latin American, of mixed background, or that 144 belonged to other racial groups (a category that included Southeast Asian, Filipino, West 145 Asian, and minorities not identified elsewhere), had significantly lower odds of vaccination 146 than those in the White/Caucasian group (ORs and CIs=0.28 [0.16,0.51], 0.27 [0.16,0.45], 0.40 147 [0.21,0.76], 0.53 [0.30,0.92], 0.23 [0.15,0.36]). Additionally, individuals that reported living in 148 the Central and West Health Regions had higher odds of vaccination than those in the Health 149 Region of Toronto (ORs and CIs=1.61 [1.10,2.34], and 1.59 [1.16,2.19], respectively). 150

²Pearson's Chi-squared test

²⁹ Southeast Asian, Filipino, West Asian, and minorities not identified elsewhere according to the Census.

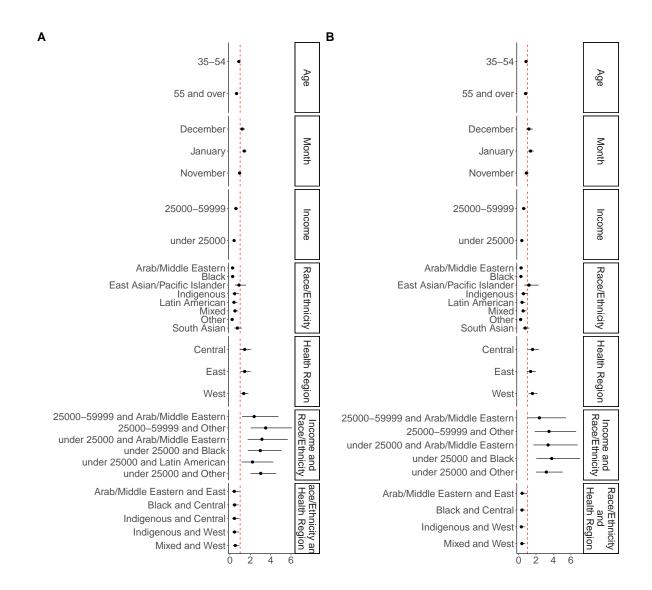

Figure 2: Coefficient estimates and confidence intervals for the uncorrected model. Only statistically significant interaction terms are shown. Full interaction terms can be found in Supplementary Figure A-3.

Interestingly, individuals in equity-deserving groups with a household income below CAD 25,000 had higher odds of vaccination (when compared to those with a household income above CAD 60,000). This held true in the case of Arab/Middle Eastern (OR=34, CI=[1.70,6.79]), Black individuals (OR=3.81, CI=[2.05, 7.09]), or those in other racial or ethnic groups (OR=3.19, CI=[2.00,5.09]). Additionally, individuals with an income between CAD 25,000 and 59,999 in the Arab/Middle Eastern and other racial ethnic groups had higher odds of vaccination (ORs and CIs=6.96 [2.67,18.16], and 3.5 [1.85,6.62]).

Finally, significantly lower odds of vaccination were identified (when compared to the Toronto Health Region) for Black individuals in the Central Health Region (OR=0.39, CI=[0.2,0.75]), Arab/Middle Eastern individuals in the East Health Region (OR=0.41 [0.17, 0.98]), and in the Indigenous and mixed groups in the West Health Region (ORs and CIs=[0.31 [0.14, 0.7] and 0.38 [0.19, 0.76], respectively).

163 Discussion

had significantly higher odds of vaccination than those in the Health Region of Toronto

Between 2007 and 2019, healthcare in Ontario was managed by 14 different LHINs, which aimed to provide an integrated health system for the province. However, this approach faced chronic problems such as fragmented electronic health systems⁴⁶, the decline of performance indicators (e.g., increased unplanned emergency visits, number of patient readmissions), and inequities in health services access⁴⁷. Based on these problematics and with the intent of better organizing and delivering care, the provincial government moved to the Health Region model in late 2019³⁵.

In this study we hypothesized that differences in COVID-19 vaccination uptake were present between the Health Regions, aiming at determining which socio-demographic groups could be impacted by these disparities in order to provide decision-makers with information that could be used to develop policies focused on reducing or eliminating these differences and ensure that the Health Region model is able to fulfill its missing of improving health access for the inhabitants of Ontario.

Our results show differences in odds of vaccination in individuals across certain socio-178 demographic groups. Specifically, those who identified as Arab/Middle Eastern, Black, Latin 179 American, having mixed racial or ethnic background, or that belonged to other groups not 180 explicitly included in the survey (Southeast Asian, Filipino, West Asian, and minority groups 181 not identified elsewhere) had vaccination odds that were between a third and a half of that 182 of individuals that identified as White/Caucasian (Figure 2). These results are consistent 183 with previous studies that have shown lower vaccination rates in individuals with the same 184 socio-demographic characteristics^{18–20,48}. 185

Lower vaccine uptake in the socio-demographic groups indicated above may be influenced in part, by vaccine hesitancy and refusal, which have been associated in equity-deserving

Canadian individuals to concerns on vaccine safety, effectiveness, and experiences of racial discrimination in health settings^{39,49-51}. However, it has been shown that structural barriers 189 also play an important role in vaccination uptake. In the case of equity-deserving individuals, 190 such barriers include complex scheduling systems, language barriers, lack of adequate public 191 transportation, and lack of accessible vaccination sites⁵². In this regard, it is interesting to 192 note that vaccination venues were scarce in low socio-economic areas that had the highest 193 burden of COVID-19 in Toronto and other regions of Ontario around the time covered by 194 the survey^{7,53}, and that pharmacies in the Peel region (an area identified as a "hotspot" with 195 high numbers of essential workers and multigenerational households) could not keep up with 196 demand⁵⁴. However, to the best of our knowledge, there seems to be a very limited amount of 197 studies in this area, indicating an ongoing need of future studies that examine the longitudinal 198 impact of vaccine accessibility and structural barriers that affected equity-deserving groups 199 within the province. 200

Although overall self-reported vaccination rates were found to be statistically significantly lower 201 in various racial minority groups when compared to White/Caucasian individuals, the change 202 in odds of vaccination within certain racial groups and income strata was actually positive, 203 in contrast to the White/Caucasian group, where vaccination odds decreased in lower income 204 brackets (when compared to the CAD 60,000 and over bracket, Supplementary Figure A-5). 205 Specifically, individuals in low income brackets that belonged to Arab/Middle Eastern, Black, 206 or other minority groups had higher odds of vaccination that their peers with an income above 207 60,000 CAD.208

This result is likely due in part to the fact that individuals that belong racial minority 209 groups tend to perform occupations that have been deemed as "essential" in the context of 210 the pandemic^{55,56}, which include grocery store workers, gas station, warehouse, distribution, 211 and manufacturing workers, all being occupations for which an income within the signifi-212 cant brackets identified in the analysis is to be expected. In Ontario, these workers had 213 priority for COVID-19 vaccination⁵⁷; and interestingly, there is evidence of interventions by 214 vaccination staff in certain parts of the province to encourage vaccination uptake by these 215 individuals⁵⁴. These facts, combined with evidence of increased trends in vaccination in this 216 group elsewhere⁵⁸, suggest that the type of occupation from individuals in equity-deserving 217 groups played an important role in increasing the odds of vaccination in the province. 218

Additionally, the interaction effect of Health Region and race was also significant in the case of individuals identifying as Indigenous or with mixed racial background in the West Health Region, Black individuals in the Central Health Region, and Arab/Middle Eastern individuals in the East Health Region Figure 2. In these cases, vaccination odds were lower when compared to those of individuals in the Toronto Health Region (Supplementary Figure A-6).
Although these findings are likely the result of multiple causes, we would like to indicate some contributing factors that might help provide context in each case.

First, it is interesting to note that the LHINs with most observations for Indigenous individuals and those with of mixed racial background in the West Health Region were the LHINs of Hamilton Niagara Haldimand Brant, South West, and Waterloo Wellington. Previous research has identified health disparities in these regions, such as unequal distribution of primary care providers, increased mortality, and low pharmacist availability^{59–61}.

According to Ontario Health, 13.2% of the population in the West Health Region identifies as a 231 visible minority, whereas 2.5% identifies as Indigenous⁶². Therefore, the estimated lower odds 232 are likely to be explained from a socio-economic perspective. In fact, 50% of the answers from 233 this region in the survey came from the former LHINs of Hamilton Niagara Haldimand Brant, 234 and Erie St. Clair, both which are among the regions of Ontario with the highest proportion of their population (more than 20%) in the lowest income quintile⁶³ (Supplementary Table A-7). 236 Interestingly, a disproportionate number of COVID-19 cases and low vaccination rate (under 237 50%) have been also reported in the South Asian community of Ontario⁶⁴. These results 238 provide context to the observed differences in vaccination among the Health Regions of the 239 province, showing which equity-deserving and socio-demographic groups in certain regions need 240 to be prioritized in future vaccination strategies. Moreover, these results provide a rationale 241 for future studies that explore how vaccination uptake varies across different minority groups within Ontario and other Canadian provinces. 243

Additionally, significant higher vaccination odds were identified in the West Health Region 244 when compared to the Health Region of Toronto (?@fig-model-corr). The West Health 245 Region comprises the regions of Waterloo and Niagara, the counties of Wellington, Essex and Lambton, and the cities of Hamilton, Haldimand, Brant, and Chatham-Kent. In this case, 247 these results could reflect the fact that in the survey, about half of the entries for this Health 248 Region corresponded to White/Caucasian individuals, who reported a vaccination rate of 83% 249 (Supplementary Table A-6). However, the interaction effect of Health Region and race was 250 also significant in the case of individuals identifying as South Asian or other minorities not 251 included in the survey ?@fig-model-corr. In this case, the results of the interaction term in 252 the model indicate that the odds of vaccination for those within the South Asian and Other 253 minority groups in the West Region decreased when compared to the other Health Regions 254 (Supplementary Figure A-6). 255

256 I

From one side, it is important to mention that historically, the social composition of the areas now covered by each Health Region (and previously by the LHINs) has been very different, and

260 and we would like to focus on two areas that might help contextualize the observed reduced 261 odds of vaccination. In the case of the West Health Region,

²⁶² The rationale behind these results its likely to be dual.

The West Health Region is located in the leftmost southern part of the province, including the regions of Waterloo and Niagara, the counties of Wellington, Essex, and Lambton, and the cities of Hamilton, Haldimand, Brant, and Chatham-Kent. The Central Health Region includes the regions of Peel and Halton, the regional municipality of York, the district of Muskoka, the counties of Dufferin, Simcoe, Grey, and the city of Etobicoke.

According to Ontario Health, 13.2% of the population in the West Health Region identifies as a visible minority, whereas 2.5% identifies as Indigenous⁶². Therefore, the estimated lower odds 269 are likely to be explained from a socio-economic perspective. In fact, 50% of the answers from 270 this region in the survey came from the former LHINs of Hamilton Niagara Haldimand Brant, 271 and Erie St. Clair, both which are among the regions of Ontario with the highest proportion of 272 their population (more than 20%) in the lowest income quintile⁶³ (Supplementary Table A-7). 273 Interestingly, a disproportionate number of COVID-19 cases and low vaccination rate (under 274 50%) have been also reported in the South Asian community of Ontario⁶⁴. These results 275 provide context to the observed differences in vaccination among the Health Regions of the 276 province, showing which equity-deserving and socio-demographic groups in certain regions need 277 to be prioritized in future vaccination strategies. Moreover, these results provide a rationale 278 for future studies that explore how vaccination uptake varies across different minority groups 279 within Ontario and other Canadian provinces. 280

303

304

305

There are some limitations to the present study. First, the data collection design, which allowed respondents to withdraw from the survey at any point, resulted in a high number of unique entries in the survey with multiple missing answers. Because we focused on entries that had complete observations in the covariates of interest for our analysis, it is possible that some information was not considered by excluding observations that had information in other variables (such as work from home, or number of persons in the household). However, we attempted to minimize this possibility by correcting the dataset using information from the Census. More granular corrections, which for example could be based on demographic information by municipality, could be used in the future to obtain a more accurate approximation to the population totals of the province. Moreover, our analysis did not consider the North West and North East Health Regions, due to the low number of entries from these areas in the survey (Figure 1). Although low representation from these areas is based on the fact that these regions only account for 5\% of the total population of Ontario, these regions are the home to more than 100,000 individuals that identify as Indigenous⁶², a minority group that has historically suffered from reduced access to health care and discrimination²¹. Therefore, there is a need for additional studies that focus on these low-populated Health Regions in Ontario where disparities in vaccination might be significant and understudied.

It is also worth mentioning that province-wide vaccination rates for the period of interest are somewhat different from those of the survey, particularly in the case of those 55 years of age and older, which in the survey had a vaccination rate of 72%, against a rate of 88.4% reported for the closest age bracket (50 years of age and older) reported by Public Health Ontario at the start of the period covered by the data⁶⁵. However, we found good agreement between the estimates from the model and overall vaccination rates reported for Canada, which have been relatively higher when compared to other high income countries⁶⁶, and with vaccination uptake rates across different age groups presented in other studies^{18,67}.

In other words, although vaccination rates obtained from the survey were slightly lower than the provincial estimates, these values still represented a valid approximation to overall trends; this notion is reinforced by the consistency in the proportion of vaccination rates (Table 1) and

vaccination odds (?@fig-model-corr) across the period covered by the survey, which closely 309 match the vaccination rates from Public Health Ontario and which indicate that due to the 310 relatively high coverage achieved in the population at that point, vaccination rates increased 311 by around 3% across all age groups during the three months covered by the survey⁶⁵. It 312 is also important to mention that to this day, differences in vaccination rates within the 313 province continue. As of March of 2023 some regions still have less than 75% vaccination 314 rate⁶⁸, and although data for the period analyzed in this study is not publicly-available, it is 315 likely that differences in vaccination rates were higher at the time, being partially captured by 316 the survey. 317

The results in this study are based on self-reported data, where bias might be present. However, 318 because in the context of COVID-19 it has been shown that good agreement exists between self-319 reported and documented vaccination status⁶⁹, we believe that our data was able to provide 320 a valid assessment of vaccination in the province. Finally, this study focused on first-dose 321 vaccination status within a relatively short time window, and therefore can only provide a 322 snapshot of the societal dynamics behind the pandemic. Nonetheless, the results presented 323 here can serve as a starting point to motivate the collection of robust longitudinal data that can 324 be used to quantify geographical and temporal differences within vulnerable segments of the 325 population, and that can be used to inform the development of adequate public health policies 326 within the province of Ontario or across other provinces that aim to minimize disparities in 327 health access. 328

Conclusion

This study explored differences in COVID-19 vaccination across the province of Ontario during 330 the last quarter of 2021 taking into consideration socio-economic factors, such as income and 331 race, their interactions, and the Health Regions within the province. Our results show that 332 during the period analyzed, differences in vaccination uptake existed across multiple equity-333 deserving groups in the province, and that these differences were significant in two of the 334 Health Regions analyzed. It is important that future public health policies in Ontario take 335 into consideration how to adequately reach individuals from equity-deserving groups that might 336 live in areas of the province where access to healthcare might be difficult. Only in this way the 337 goal of the Health Region model, which aims at reducing disparities, will become successful. 338
